

Current explicit expressions for $N_d(\lambda)$ with $n = m$

For 1 row tabloids (as in $\lambda = n$), $N_d(\lambda) = 1$

For 2 row tabloids (see calculations on 5/30), I *thought* I found an expression. This expression was wrong.

For partitions of the form $\mu = 1^{n-k}k$, I found

$$N_0(\mu) = \sum_{s=1}^{n-k+1} \binom{n-s}{k-1} = \binom{n}{k}$$

Then more generally,

$$N_d(\mu) = \begin{cases} 0 & d \geq k \\ \sum_{s=d+1}^{n+d-k+1} \binom{s-1}{d} \binom{n-s}{k-1-d} = \binom{n}{k} & d < k \end{cases}$$

Question: For $M = 1^{\text{nk}} K$, what is $N_d(M)$?

defect $d \geq k$: not possible $\Rightarrow N_d(M) = 0$

ex: defect 0: given the k part is at spot s :

We have

$$\sum_{s=1}^{n-k+1} \binom{s-1}{s-1} \cdot \binom{n-s}{n-k-(s-1)} = \sum_{s=1}^{n-k+1} \binom{n-s}{n-s+k-1} = \sum_{s=1}^{n-k+1} \binom{n-s}{k-1} = \binom{n}{k}$$

defect $d < k$ given the k part is at spot s :

$$\sum_{s=d+1}^{n-d+k+1} \binom{s-1}{d-1} \binom{n-s}{n-k-(s-1-d)} = \sum_{s=d+1}^{n-d+k+1} \binom{s-1}{d-1} \binom{n-s}{k-1-d} = \binom{n}{k}$$

We can also prove via induction:

(1) $\binom{1}{0} = 1 \cdot 1 = 1$
(2) $\binom{2}{1} = 2 \cdot 1 = 2$
(3) $\binom{3}{2} = 3 \cdot 2 = 6$
 \dots
(4) $\binom{4}{3} = 4 \cdot 1 = 4$

20

$d=1, n-k=3, n=6, k=3$

$4 \cdot 1 + 3 \cdot 2 + 2 \cdot 3 + 1 \cdot 4$

Conversations with Prof O 6/6 and 6/7

From 6/6

- We thought a little bit about what happens if the parking lot is circular rather than linear. In this sense, every car will end up parked somewhere, so when $n = m$, you will always get a permutation. In terms of applications, this parallels the original application of linear probing. On the board, computed permutations for $n = 3, m = 3$.
 - One choice is where the cars get back in line - do cars return to the end of the line or continue to park immediately? Or some intermediate (think Ontario airport pick up)
 - Used these counts to get a permutation statistic on S_n . It turns out that for $n = m = 3$ and linear probing as a procedure (every car parks on its turn), the number of preference lists which give rise to a certain permutation is a class function (which can then be decomposed into characters).
 - This conversation also led towards thinking of data on a cube or on a circular cube, which begs the question of how does a function decompose in \mathbb{Z}_3^n , and is it high or low frequency? (seems like defect would be low frequency on a cube/hypercube)
 - My writing in red are my questions after 6/6
 - A small result: for a preference list π with defect d , $d \leq n - (\text{filling}(\pi) \cdot n)$ this is $\text{filling}(\pi) \cdot n$ is the car occupying the last spot. Before this car parks, every other car must have been able to park.

From 6/7:

One of the things that was difficult for the comparison to rook monoids earlier was that we didn't have a module homomorphism, so we lost several tools. This raises the question of if there are particular subgroups of $C_n \wr S_m$ which behave nicely and do give module

homomorphisms. On the left of the board, there is some investigation of what subgroups might behave nicely.

If we call P the map which sends preference lists to permutations This raises the question, what is the largest subgroup of $C_n \wr S_m$ which commutes with P ?

Not on the board was some of the visualizing of subgroups and statistics that I thought through because drawing in 3d is hard. Here are some fun visualizations

- Orbit of the diagonal subgroup are all diagonal lines which cut through a hypercube at an angle
- I'm fairly sure that orbits of S_m are all contained within hyperplanes which are normal to the lines formed by orbits of the diagonal subgroup. For example - think about the set of all permutations in S_3 as a part of the 3 by 3 hypercube
- Luck is constant on orbits of the diagonal subgroup
- Defect is constant on orbits of S_m . In particular for $n = m = 3$, defect is 0 on and below the plane formed by the permutations, 1 in the space above and in the middle of this plane, and 2 only at the top corner. One way that you could notate this more clearly is by defining a relation $<$ where $\pi < \rho$ if $\pi_i \leq \rho_i$ for all i and $\pi \neq \rho$. Let $D(\pi)$ be a function which returns the defect of π . Then if $\pi < \rho$ then $D(\pi) \leq D(\rho)$

Ideas to understand better

Ideas and theory which Prof O brought up/mentioned/explained. Mackey theory, double cosets (versus two sided cosets), Gelfand pairs, induced representations relate to tensor products. It would be interesting to investigate if there are two sided cosets of $C_n \wr S_m$ on which some of our functions of interest are constant.

- Two sided cosets relate to indicator functions like in Brendon and Rhoades to define locality: aHb with $a, b \in G$ is a two sided coset of H in G . Two sided cosets always have the same size and cover the space, but do not partition it.
- Double cosets are of the form HxK . Double cosets partition G like cosets, but might be of different sizes. The subgroup of $H \cap K$ which commutes with x plays an important role in figuring out the size of the coset. Note that $\max(|H|, |K|) \leq |HxK| \leq |H||K|$
- Gelfand pairs relate to double cosets HxH . Apparently, the set of functions which are constant on 2 sided cosets are closed under convolution, and Gelfand pairs correspond to that algebra being commutative. Also to induced representations being multiplicity free
- In terms of thinking about the module decomposition - you could relate things to the trivial representation of S_m induced to $C_n \wr S_m$ then restricted to S_m again. (haha should've taken better notes silly)

- Another way to think of inducing representations is to take the tensor product $\mathbb{C}G \otimes_{\mathbb{C}H} M$.
-

Number of circular preference lists is NOT a class function

In my discussions with prof O and testing for 3 element lists, this permutation statistic was a class function for $n = m = 3$. It turns out that it is not a class function for $n = m = 4$. This makes sense because one of the defining features of this function was that it was constant on cosets of cyclic subgroup of S_m generated by the shift operator. This happens to give a class function for S_3 , but doesn't play nicely with conjugacy classes in general.
